Short Title: Host Biomarkers of IPA

#Address correspondence to David S. Perlin, perlinds@njms.rutgers.edu
Invasive pulmonary aspergillosis (IPA) is a life threatening disease of immunocompromised patients that requires aggressive therapy. Detection and monitoring therapeutic response during IPA is complex and current molecular diagnostics are not suitably robust. Here, we explored proteomic profiles of bronchoalveolar lavage fluid (BALF) specimens from a persistently neutropenic rabbit model of IPA. Three experimental arms: uninfected control animals, infected untreated animals, and animals infected and treated with ravuconazole/amphotericin B were studied. Total proteins were evaluated by 2D gel electrophoresis, followed by matrix-assisted laser desorption/ionization time-of-flight/time-of-flight (MALDI TOF/TOF) mass spectroscopy (MS) and quantified by enzyme-linked immunosorbent assay (ELISA). Host derived proteins: Haptoglobin (Hp), C-reactive protein (CRP) and Annexin A1 (Anx A1) were prominently found in BALF during the IPA infection and showed significant changes in response to antifungal therapy (p < 0.0001). In serum differences in Hp (p = 0.0001) were observed between infected and treated rabbits. Preliminary in vitro studies revealed that Aspergillus fumigatus secreted proteases may contribute to the cleavage of Anx A1 during IPA. In summary, host protein biomarkers Hp, CRP and Anx A1 may have value to monitor therapeutic response to antifungal agents in IPA patients with confirmed disease.
INTRODUCTION

Invasive pulmonary aspergillosis (IPA) caused by *Aspergillus fumigatus* is a devastating disease for immunocompromised patients. Successful management of patients depends on early diagnosis, effective therapy and monitoring of therapeutic response. Detecting IPA and monitoring response to therapy still remains very difficult especially in early stages of the disease. Currently, according to the European Organization for Research and Treatment of Cancer/Invasive Fungal Infections Cooperative Group and the National Institute of Allergy and Infectious Diseases Mycoses Study Group (EORTC/MSG), diagnosis of IPA relies on a positive CT scan, culture and/or microscopic evidence of disease, and detection of *A. fumigatus* antigens in a susceptible host (1).

The use of surrogate markers of infection is an important adjunct to diagnosis of IPA. The galactomannan immunoassay is commonly used in the diagnosis of this infection in patients. Yet this test has limitations for monitoring therapeutic response and it has a potential for false-positive results (2, 3, 4). In recent years, improved methodologies have been developed for detection of *Aspergillus* nucleic acid in blood and bronchoalveolar lavage fluid (BALF). Developing additional biomarkers could complement existing diagnostic methods by helping to improve detection of IPA and monitoring response of at-risk patients to therapy.

During the past several years, proteomic techniques have been used to study *A. fumigatus* during invasive infection (5, 6). However, less is known about the host proteomic profile in response to infection with *Aspergillus*. Proteomic analysis of primary
specimens such as BALF and serum can provide an understanding of complicated host-pathogen interactions during IPA.

In this pilot study, we profiled the proteome of BALF and serum samples from an experimental rabbit model of IPA. Prominent host biomarkers were identified following *Aspergillus* infection and were useful in assessing therapeutic response to antifungal agents.
MATERIALS AND METHODS

Animal model. A well described (7) persistently neutropenic rabbit model of IPA was used for the experiments. Three experimental arms consisted of uninfected control animals (n=13), infected endotracheally with A. fumigatus untreated animals (n=17), and infected rabbits treated intravenously with antifungal agents (n=16): liposomal amphotericin (LAMB) at 5 mg/kg, deoxycholate amphotericin B (DAMB) at 1 mg/kg, or ravuconazole (RVZ) at 5 mg/kg. Neutropenia was deliberately chosen for comparison of host biomarkers response during the antifungal therapy to simulate prominent condition for human infection.

Bronchoalveolar lavage. Bronchoalveolar lavage was performed postmortem on each lung preparation by the instillation and subsequent withdrawal of 10 ml of sterile normal saline twice into the clamped trachea with a sterile 12-ml syringe. The lavage was then centrifuged for 10 min at 400 × g. The upper and lower (2 ml) portions of the supernatant were transferred into centrifuge tubes, and stored at -80°C.

Serum collection. Serum specimens (1 ml) were collected from infected untreated and treated rabbits on postinoculation days (PID): 0, 1, 4, 6, and 13 and stored at -80°C. Serum specimens for uninfected control rabbit arm were collected from healthy rabbits and stored at -80°C.

2D gel electrophoresis and protein identification. Total proteins in BALF samples were evaluated by 2D gel electrophoresis as previously described (8). Protein spots of interest were excised from the gel, trypsin digested and analyzed by mass spectroscopy (MS) on a 4800 matrix-assisted laser desorption/ionization time-of-flight/time-of-flight (MALDI TOF/TOF) mass analyzer. Protein identification was
performed by searching the combined tandem mass spectra against the NCBI (National Center for Biotechnology Information) mammals sequence database, using a local MASCOT search engine (V. 1.9) on a GPS (V. 3.5, ABI) server.

**The enzyme-linked immunosorbent assay (ELISA).** ELISA was performed using Human Haptoglobin ELISA kit (GenWay), Rabbit CRP ELISA kit (Immunology Consultant Laboratory, Inc) and Rabbit Annexin A1 ELISA kit (Uscn Life Science Inc.) following manufacture’s protocol.

**A. fumigatus growth conditions.** *A. fumigatus* wild type R21 strain was grown for 4 days at 37°C on potato dextrose agar (PDA; Becton Dickenson, Sparks, MD). At the end of the incubation period conidia were harvested with 0.01% Tween-20 solution. For degradation assays, 100 ml of *Aspergillus* minimal medium (AMM) were inoculated with $1 \times 10^8$ conidia and incubated at 37°C with shaking (225 rpm) for 72 h.

**Annexin A1 degradation assay.** Five milliliters of 72 h-old *A. fumigatus* culture were filtered through 0.45-µm filter (Fisher Scientific) to separate conidia and hyphae from the culture supernatant. Two micrograms of purified Recombinant Human Annexin A1 (RD Systems) or 10 µl of K-562 (Human erythromyeloblastoid leukemia cell line) (Santa Cruz Biotechnology, Inc.) whole cell lysate were added to 20 µl of *A. fumigatus* culture filtrate. The solutions were incubated at 37°C for 2 h and Western blotting of the samples was performed.

**Western blotting.** Samples were separated by SDS-polyacrylamide gel electrophoresis (SDS-PAGE) and transferred to a polyvinylidene difluoride (PVDF) membrane (Invitrogen) using iBlot Gel Transfer Device (Program 3) (Invitrogen). After the transfer, cleavage products were detected by Western blotting using iBlot Gel
Transfer Device (Program 9) and iBlot Western detection kit (Invitrogen). Annexin A1 monoclonal antibodies (EMD Millipore) were used for the detection in a dilution of 1:1,000.

Statistical analysis. Comparisons between two groups were made by Fisher's exact tests for categorical variables and Mann-Whitney test or unpaired t-test for continuous variables. Multivariate analysis of variance (ANOVA) was performed to compare continuous variables repeatedly measured at multiple time points among different groups. Significance was defined as a P value ≤ 0.05 (two-tailed).
RESULTS

Identification of BAL host proteins responding to infection and therapy by 2D gel electrophoresis. BALF samples from uninfected controls, infected untreated and treated rabbits were analyzed by 2D gel electrophoresis in which the samples were first separated on a pH 5-8 linear gradient followed by 12.5% SDS-PAGE in second dimension. Figure 1 shows a typical 2D gel after staining with SYPRO ruby. The images of 2D gels were analyzed using PDQuest 2.3 to determine those prominent proteins responsive to both IPA infection and subsequent therapy. Proteins corresponding to spots 1, 2 and 3 were absent in BALF from healthy animals, appeared with strong signals in samples from infected rabbits, and disappeared in samples collected after the treatment. In contrast, the protein level at spot 4 decreased following IPA infection and was partially restored after therapy.

Protein spots of interest 1, 2, 3 and 4 were excised from the gel, trypsin digested and analyzed by MALDI TOF/TOF MS. The MS analysis revealed that spot 1 was Haptoglobin (Hp), spots 2 and 3 were found to be C-reactive protein (CRP), and spot 4 was identified as Annexin A1 (Anx A1). Spots 2 and 3 represented the same protein (CRP) possibly due to the proteolytic cleavage of CRP subunits or various posttranscriptional modifications.

Three proteins listed above appeared to respond to IPA infection, as well as to treatment with antifungal drugs. Therefore, they were chosen as potential host-based biomarkers of IPA useful in monitoring therapeutic response.

Quantification of host biomarkers in BALF. To quantify the amount of Hp, CRP and Anx A1 in rabbit BALF samples, ELISA was performed for each protein.
biomarker (Figure 2). Hp abundance in BALF from infected untreated rabbits was highly pronounced (10.8 ± 2.1 µg/ml), while it was minimal in BALF from uninfected and treated animals (0.14 ± 0.10 µg/ml and 0.44 ± 0.19 µg/ml respectively). The level of Hp in BALF from rabbits with IPA was significantly greater than either that of uninfected or treated animals (p < 0.0001) (Figure 2A). There was no significant difference in Hp between the uninfected control and treated groups (p > 0.05). CRP was detected in 16 (94%) of 17 samples of infected untreated rabbits (14.84 ± 2.41 µg/ml) and undetectable in 100% of BALF from uninfected control animals (Figure 2B). In treated animals, CRP was found in 1 (6%) of 16 samples (0.1 ± 0.06 µg/ml). The amount of CRP in BALF from infected untreated rabbits was significantly higher than in the samples from uninfected and infected-treated animals (p < 0.0001). Anx A1 level was significantly lower in BALF from infected untreated rabbits (0.11 ± 0.02 µg/ml) than in the samples from control (1.99 ± 0.25 µg/ml) and treated animals (1.83 ± 0.19 µg/ml), (p < 0.0001) (Figure 2C). There was no significant difference found between ravuconazole and amphotericin B treatment in terms of the three biomarkers profiles. Both drugs led to reduced levels of Hp and CRP and restored level of Anx A1.

**Abundance of putative host biomarkers in serum.** The abundance of all three biomarkers in serum was measured by ELISA and compared in cohorts of uninfected control, infected untreated and treated animals (Figure 3). While serum was collected from all treated rabbits at specified time points (PID 0, 1, 4, 6, 13), only a few samples or none were collected from the untreated infected animals on or after PID 6 due to euthanasia using humane endpoints.
Anx A1 was undetectable in serum from all three groups of animals. Hp and CRP were mainly found in serum from both infected untreated and treated rabbits at all time points except day 0 (baseline). As shown in Figure 3, serum Hp levels appeared to increase with the progression of infection and decrease in response to treatment. Serum CRP levels showed an upward trend in 6 of 7 untreated rabbits and decreased with antifungal therapy.

The time courses of each protein biomarker were compared between infected untreated and treated groups. Examination of the estimated marginal means indicated that serum Hp concentrations were not significantly different between infected untreated and treated rabbits from PID 0 to 4. On PID 6, however, serum Hp concentration in treated animals was significantly lower than that in untreated animals (F = 17.831, p = 0.0001). Serum CRP showed no significant difference between infected untreated and treated rabbits from PID 0 to 6. However CRP concentration in serum showed a downward trend in response to antifungal treatment from PID 6 to 13.

Effect of *Aspergillus fumigatus* secreted proteases on Anx A1. To test whether *A. fumigatus* plays a role in Anx A1 degradation, supernatant of a 5 ml 72-h-old *A. fumigatus* liquid culture was filtered and subsequently incubated with purified Anx A1 (Figure 4A, lane 3), as well as with K562 cell line lysate (Figure 4A, lane 1) for 2 h at 37°C. Cleavage of Anx A1 was visualized by Western blotting. The analysis showed that after 2 h incubation Anx A1 was completely degraded (Figure 4A, lane 4). In the case of K562 cell lysate incubation, low molecular weight products were visible (Figure 4A, lane 2).
Different volumes of *A. fumigatus* culture filtrate were incubated with K562 cell line lysate to investigate if different cleavage products could be obtained depending on the volume of culture filtrate added (Figure 4B). When a volume of culture filtrate higher than 10 µl was added to K562 cell lysate, it resulted in cleavage of Anx A1 into four major low molecular weight products (Figure 4B, lanes 3 to 5). Degradation of Anx A1 also was observed after incubation with 5 µl of culture filtrate but it was less prominent (Figure 4B, lane 2). After incubation with 2.5 µl of culture filtrate the protein remained intact (Figure 4B, lane 1).
DISCUSSION

The development of host biomarkers of IPA may provide better understanding of disease, improve diagnostics, and help monitor treatment response. In this pilot study, we identified several biomarkers that responded to infection and subsequent therapy.

Hp levels were found to be high in BALF from rabbits with IPA infection and significantly decreased after the treatment (Figure 2A). Hp is an acute phase protein, which takes part in various processes of immune responses including activation of the innate and adaptive immune response, tissue repair and regeneration. Hp release induces leukocyte activation, modulation of cytokine patterns, prostaglandin synthesis, and tissue repair (9). Hp has a bacteriostatic role by binding hemoglobin and preventing the utilization of iron by pathogenic bacteria that require iron for their growth (10). Iron uptake is crucial for *A. fumigatus* growth in the lung environment (11). Thus, high levels of Hp during IPA suggest the host sequestration of iron to prevent its use by *A. fumigatus* along with immunomodulatory response to the infection.

*A. fumigatus* secretes large quantities of hemolysin (12). During IPA, angioinvasion results in hemorrhagic infarction and release of hemoglobin. The importance of host response of releasing Hp to bind hemoglobin during invasive aspergillosis was recently reported by Goetting *et al* who found that plasma iron was significantly increased in infected animals (13). *Fusarium* infection also has been associated with elevated Hp concentrations in the tears of patients with fusarial keratitis (14). Given the increasingly recognized role of Hp in invasive mycoses, understanding its role as a host-based diagnostic biomarker of therapeutic response is important. Combining an organism-based biomarker, such as galactomannan, for measuring
therapeutic response (15) with a pathophysiologically based host biomarker, such as Hp, may further strengthen our ability to assess therapeutic efficacy and predict outcome.

The analysis of rabbit BALF specimens during IPA also revealed a substantial increase of another acute phase protein CRP (Figure 2B). It is noteworthy that CRP levels in BALF from treated rabbits were almost undetectable, which makes it a promising marker to monitor response to antifungal therapy. At the molecular level, production of CRP is induced by proinflammatory cytokines IL-1, IL-6, and IL-17 in the liver in response to microbial infection, tissue injury, and autoimmune disorders. (16). Human endothelial cells and murine macrophages exposed to CRP in vitro express chemokine MCP-1 (17). CRP acts as an opsonin supporting ingestion of apoptotic cells by human macrophages and plays a role in the clearance of apoptotic cells, especially during acute phase reactions (18, 19). Our data is consistent with other studies that also detected high level of CRP in BALF during the fungal infections (20, 21).

Finally, our study indicates that Anx A1 levels in BALF from infected rabbits were significantly reduced compared to samples from uninfected and treated animals (Figure 2C). Anx A1 is a member of a phospholipid and calcium binding family of proteins. Large amounts of this protein were found in BALF from normal volunteers while the degradation of Anx A1 was seen in cystic fibrosis patients (22, 23). Both Anx A1 and its biologically active N-terminal peptide are considered to be modulators of systemic anti-inflammatory processes (24, 25). It has been shown that the amounts of Anx A1 increase in response to corticosteroid treatment (26), suggesting an essential role during the inflammatory processes in the lungs. The major site of IPA infection is the lungs, which contains abundant Anx A1 (27). Thus, inactivation of Anx A1 might be
critical for *A. fumigatus* growth, considering its regulatory role during the anti-inflammatory pathway. We demonstrated that culture filtrate from *A. fumigatus* possessed proteolytic activity towards Anx A1 *in vitro* (Figure 4). Our study suggests that secreted proteases of *A. fumigatus* may play role in Anx A1 cleavage. However, additional experiments are needed to establish the specificity of the observed cleavage.

The fact that Anx A1 was undetectable in serum from all three groups of animals (uninfected, infected untreated and treated) suggests that it is a biomarker of local inflammation rather than circulating infection. Nevertheless, the state of Anx A1 might still reflect treatment response during IPA using BALF. In contrast, Hp in serum displayed time-dependent patterns associated with IPA development, as well as with response to antifungal therapy, while in healthy normal rabbits it was undetectable (Figure 3A). The level of circulating Hp was increasing with the progression of infection and subsequently decreasing in treated rabbits with significant difference on PID 6 of the study (*p*=0.0001). Therefore, further exploring Hp kinetics may provide additional information on disease progression as well as therapeutic response to antifungals. CRP was found in serum collected from both infected untreated and treated rabbits, but not from uninfected healthy rabbits. There was no significant difference in CRP serum concentration between untreated and treated groups from PID 0 to 6; however the level of protein was decreasing in response to antifungal treatment during the remaining study period (PID 6 to 13) (Figure 3B).

Our findings suggest that host proteins Hp, CRP and Anx A1, which play important roles in host defense mechanisms during the pathogenesis of IPA, may have value for monitoring therapeutic effect on patients who were diagnosed with IPA.
according to EORTC/MSG diagnosis criteria. Once a definite diagnosis of IPA is made, these biomarkers could be useful in guiding antifungal treatment. However the response of these biomarkers to both infection and antifungal therapy requires further study.

In conclusion, a proteomic approach was used to identify potential host protein biomarkers of IPA that are responsive to therapy. Detection of the prominent host proteins: Hp, CRP and Anx A1 may have value to monitor antifungal therapeutic response in patients with IPA.

**Figure 1.** 2D gels of bronchoalveolar lavage fluid (BALF) samples. An aliquot of 50 µg of protein was subjected to 2-dimensional gel electrophoresis using strips of pI 5 to 8 followed by 12.5% SDS-PAGE gel in second dimension. The marked spots were excised, trypsin digested, and analyzed by MS. Spot 1 – Haptoglobin (Hp), spots 2, 3 – C-reactive protein (CRP), spot 4 – Annexin A1 (Anx A1). (A) BALF from infected untreated animal demonstrates abandon presence of both Hp and CRP, whereas Anx A1 is almost undetectable. (B) BALF from treated rabbit is characterized by the absence of Hp and CRP with the presence of Anx A1 (similar to the uninfected control). (C) BALF from uninfected control (healthy rabbit) shows the absence of Hp and CRP, while Anx A1 is present. Gels were stained with SYPRO ruby for visualization.

**Figure 2.** Histogram of Haptoglobin (Hp), C-reactive protein (CRP) and Annexin A1 (Anx A1) ELISA results (mean of three tests) for bronchoalveolar lavage fluid (BALF) from uninfected control (n=13), infected untreated (n=17) and treated (n=16) rabbits. (A) Hp concentration is high in BALF from untreated rabbits and minimal in BALF from uninfected and treated animals. (B) CRP level is abundant in BALF from untreated rabbits while in BALF from treated and uninfected animals is almost undetectable. (C) Anx A1 is present in BALF from uninfected animals, decreased following IPA infection, and restored after therapy.
